

Project: Can Individual Political Leaders Make a Difference?

Overview

In the year of the US presidential elections, the influence of individual political leaders on the course of a nation becomes a particularly relevant and pressing topic. The debate centers around whether leaders with differing ideologies and personalities can significantly impact national trajectories, or if they are largely constrained by historical contexts and institutional frameworks. Understanding the true extent of a leader's influence can inform public opinion, electoral strategies, and policy-making. Testing the influence of individual leaders is inherently difficult. The ascent of political leaders is often influenced by preceding conditions and public sentiment, making it challenging to isolate their impact. Furthermore, there are many confounding factors to be adjusted for. In this context, natural experiments can provide valuable insights into causal relationships. The natural experiment framework refers to a research design or approach in which naturally occurring events or circumstances are leveraged to study the effects of an intervention, policy, or other factors on a population. In a natural experiment, researchers do not manipulate the independent variable; instead, they observe its effects as they occur in real-life settings. This approach is valuable when random assignment to control and experimental groups is not feasible or ethical.

Goal

The goal of this project is to leverage a natural experiment framework by examining instances where the success or failure of assassination attempts on political leaders is assumed to be essentially random. We will examine the effect of a leader assassination on institutions (measured by polity score) and war.

The Data

Each observation in the dataset includes detailed information about specific assassination attempts on political leaders, encompassing both successful and failed attempts. The dataset integrates polity scores from the Polity Project, which systematically documents and quantifies regime types of countries worldwide from 1800 to the present. The polity score is a 21-point scale ranging from -10, indicating a hereditary monarchy, to 10, representing a consolidated democracy. This score provides a comprehensive measure of the political regime characteristics of a country.

Acknowledgements

Based on Benjamin F. Jones and Benjamin A. Olken (2009) "Hit or miss? The effect of assassinations on institutions and war." *American Economic Journal: Macroeconomics*, vol. 1, no. 2, pp. 55–87.

Data Column Reference

Variable	Description
country	Name of the country
year	Year of the assassination attempt
leadername	Name of the leader target of the assassination attempt
age	Age of the targeted leader
politybefore	Average polity score of the country during the three-year period prior to the attempt
polityafter	Average polity score of the country during the three-year period after the attempt
civilwarbefore	1=the country was in civil war during the three-year period prior to the attempt; 0=otherwise
civilwarafter	1=the country was in civil war during the three-year period after the attempt; 0=otherwise
interwarbefore	1=the country was in international war during the three-year period prior to the attempt; 0=otherwise
interwarafter	1=the country was in international war during the three-year period after the attempt; 0=otherwise
result	Result of the assassination attempt

Imports

153	2001	Nepal	Birendra	55	5	-6	0	0	0	1	dies within a day after the attack
53	2001	Congo Kinshasa	Laurent Kabila	62	0	0	0	0	1	0	dies within a day after the attack

250 rows x 11 columns

There are 250 assassination attempts recorded from 1878 to 2001.

```
In [15]: leaders['country'].nunique()
```

```
Out[15]: 88
```

```
In [12]: leaders['country'].value_counts()
```

```
Out[12]:
```

Japan	11
Mexico	11
France	10
Russia	10
United States	8
...	...
Oman	1
Panama	1
Colombia	1
Yugoslavia	1
Name: country, Length: 88, dtype: int64	

Eighty-eight countries have experienced at least one assassination attempt between 1878 and 2001, with Japan and Mexico experiencing the most, each having 11 attempts.

```
In [24]: leaders.groupby('year').size().mean()
```

```
Out[24]: 2.450980392156863
```

On average, there have been 2.45 assassination attempts per year.

```
In [31]: round(leaders['success'].mean() * 100, 1)
```

```
Out[31]: 21.6
```

Success of leader assassination

The overall success rate of leader assassination is 21.6%.

Cross-section comparison design

```
In [9]: # split dataset between attempts resulted in death and attempts resulted in survival
leaders_1 = leaders.query('success == 1') # treatment group
leaders_0 = leaders.query('success == 0') # control group
```

Assumption: the success rate of an assassination attempt is random. We consider the group of deceased leaders as the *treatment* group, while the group of surviving leaders serves as the *control* group.

Effect on institutions (polity score)

Cross-section comparison between successful and failed assassination attempts.

```
In [57]: # compute the difference-in-means AFTER
```

```
leaders_1['polityafter'].mean() - leaders_0['polityafter'].mean()
```

```
Out[57]: 1.131708238851096
```

Countries where a leader died have an average polity score over a 3-year period after the assassination attempt that is higher (1.13 points) than those with a failed attempt. Successful assassinations lead to greater democratization compared to failed attempts.

Effect on civil and international wars

Cross-section comparison between successful and failed assassination attempts.

```
In [65]: # compute the difference-in-means for wars AFTER
```

```
round((leaders_1['warafter'].mean() - leaders_0['warafter'].mean()) * 100, 2)
```

```
Out[65]: -9.22
```

The difference between the proportion of countries at war after a successful assassination attempt and the proportion of countries at war after a failed assassination is -9.22 percentage points. We can conclude that successful assassination attempts lead to a lower likelihood of war compared to failed attempts, on average.

In conclusion, this project has provided compelling evidence to support the notion that successful assassination attempts on leaders are associated with outcomes that promote democracy and reduce instances of war. This finding underscores the significant impact that individual political leaders can have.

Is the assumption that the success of assassination attempts is randomly determined a valid assumption?

We have already observed that the overall success rate of leader assassination is 21.6%. This result leads us to question the assumption that the success rate in an assassination attempt is randomly determined. Further exploration is warranted.

```
In [51]: leaders_1['age'].agg(['mean', 'median', 'min', 'max'])
```

```
Out[51]:
```

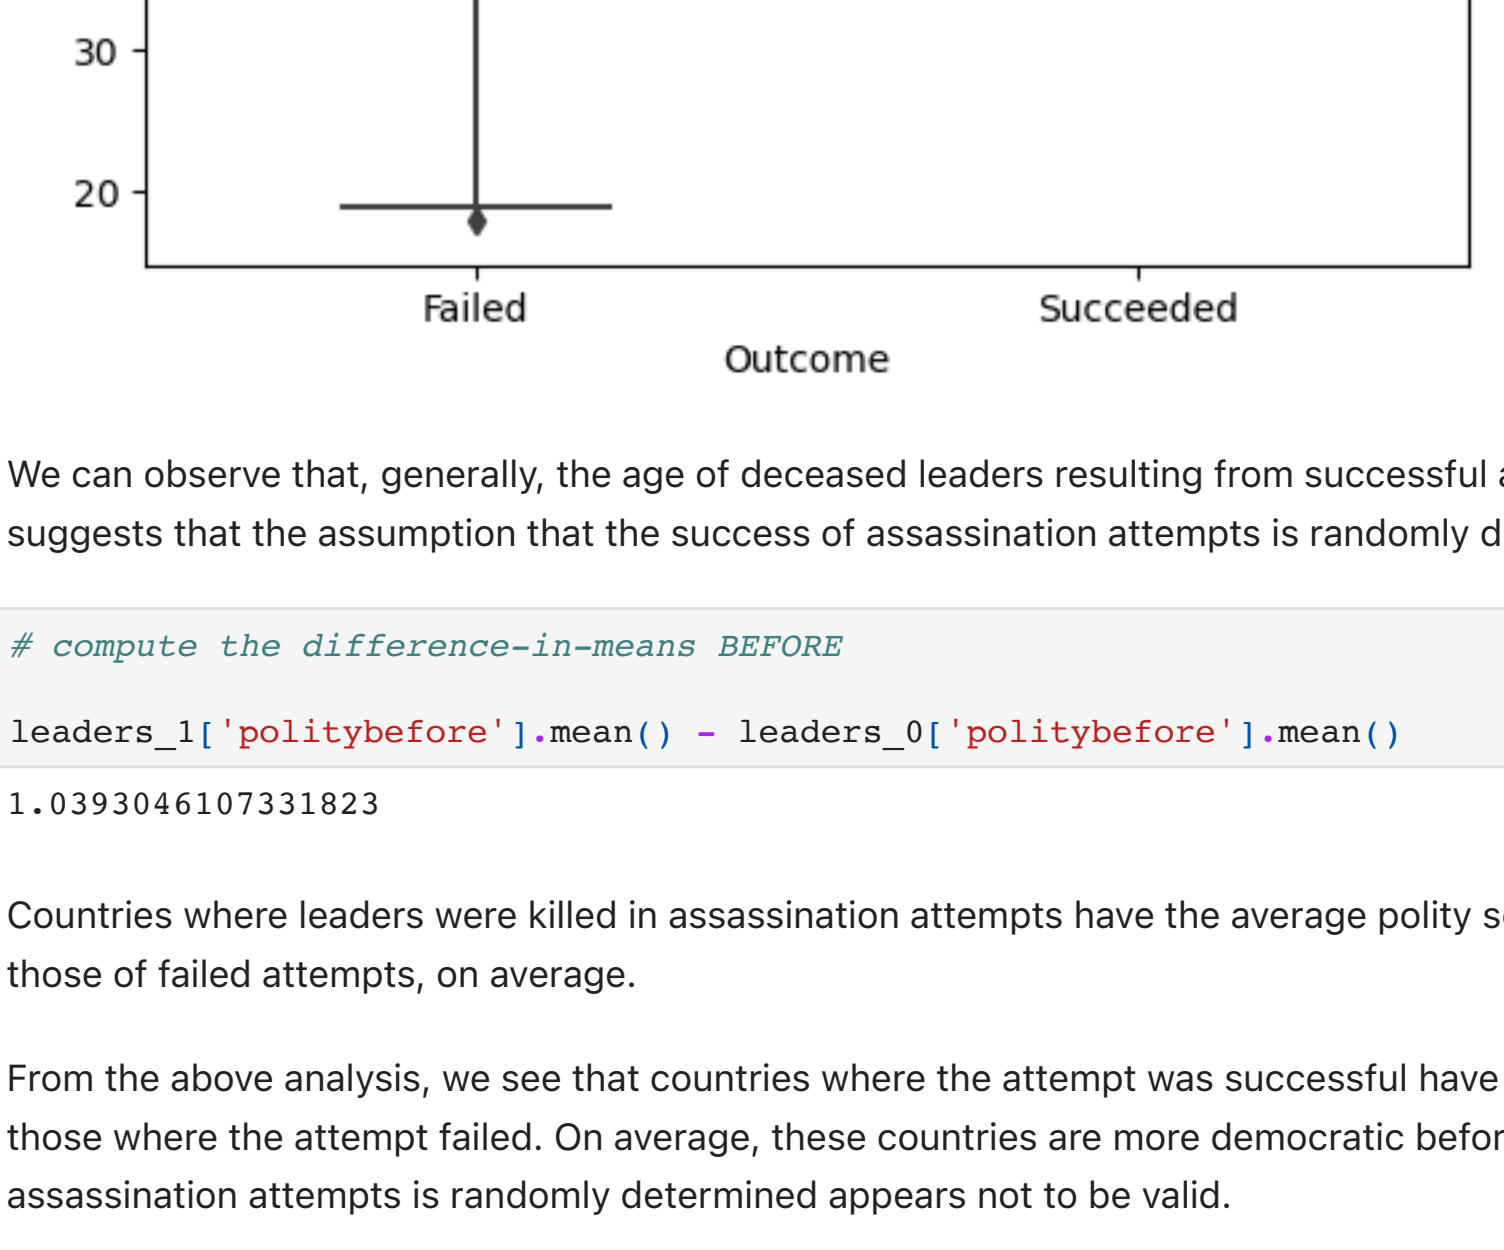

mean	56.462963
median	58.000000
min	34.000000
max	77.000000
Name: age, dtype: float64	

```
In [52]: leaders_0['age'].agg(['mean', 'median', 'min', 'max'])
```

```
Out[52]:
```

mean	52.714286
median	51.500000
min	18.000000
max	81.000000
Name: age, dtype: float64	

```
In [11]: sns.boxplot(x='success', y='age', data=leaders)
plt.xlabel('Outcome')
plt.ylabel('Age')
plt.xticks([0, 1], ['Failed', 'Succeeded']) # Customizing x-axis labels
plt.title('Age Distribution of Leaders Targeted in Assassination Attempts');
```

We can observe that, generally, the age of deceased leaders resulting from successful assassination attempts is higher than that of those who survived. This suggests that the assumption that the success of assassination attempts is randomly determined may not be valid.

```
In [56]: # compute the difference-in-means BEFORE
```

```
leaders_1['politybefore'].mean() - leaders_0['politybefore'].mean()
```

```
Out[56]: 1.0393046107331823
```

Countries where leaders were killed in assassination attempts have the average polity score in the 3-year period prior to the assassination 1.04 points higher than those of failed attempts, on average.

From the above analysis, we see that countries where the attempt was successful have a higher average polity score both before and after the attempt compared to those where the attempt failed. On average, these countries are more democratic before and after the attempt. Again, the assumption that the success of assassination attempts is randomly determined appears not to be valid.

```
In [64]: # compute the difference-in-means for wars BEFORE
```

```
round((leaders_1['warbefore'].mean() - leaders_0['warbefore'].mean()) * 100, 2)
```

```
Out[64]: -2.06
```

Since the difference between the proportion of countries at war prior to a successful assassination attempt and the proportion of countries at war prior to a failed assassination is -2.06 percentage points, we can conclude that successful assassination attempts are associated with countries with a lower likelihood of war compared to failed attempts, on average.

These results suggest that successful assassinations tend to occur when leaders are older and in countries that are more democratic and less prone to civil or international wars compared to failed attempts. This indicates that the success rate of assassination attempts may not be randomly determined.

Reduce bias.

Before-and-after design

```
In [14]: # change in outcome variable 'polity score' from pretreatment period to posttreatment period
# for successful assassination attempt

diff_polity = leaders_1['polityafter'].mean() - leaders_1['politybefore'].mean()
diff_polity
```

```
Out[14]: -0.05555555555555547
```

```
In [24]: # change in outcome variable 'war' from pretreatment period to posttreatment period
# for successful assassination attempt
diff_war = leaders_1['warafter'].mean() - leaders_1['warbefore'].mean()
round(diff_war * 100, 2)
```

```
Out[24]: -14.81
```

When using the before-and-after design, we observe that in countries where attempts are successful, the polity score decreases by an average of 0.056 after the assassination. This result contradicts the previous cross-sectional analysis, which showed an increase in the polity score.

Regarding involvement in wars, the previous cross-sectional analysis indicated a decrease of -9.22 percentage points. However, with the before-and-after design, we now see a decrease of close to -15 percentage points, indicating a stronger effect.

Difference-in-differences design (DiD)

```
In [19]: diff_0_polity = leaders_0['polityafter'].mean() - leaders_0['politybefore'].mean()
```

```
In [20]: diff_polity - diff_0_polity
```

```
Out[20]: 0.0924036281179138
```

```
In [21]: diff_0_war = leaders_0['warafter'].mean() - leaders_0['warbefore'].mean()
```

```
In [25]: round((diff_war - diff_0_war) * 100, 2)
```

```
Out[25]: -7.16
```

When applying the Difference-in-Differences (DiD) design, we find that successful assassinations might have led to a slight increase in the polity score and a decrease in the countries' involvement in wars. The DiD results are smaller than those from the cross-sectional analysis, but comparable.
